(Submitted 7 May 1991)

We calculate the scattering length for transitions between edge states in two-dimensional electron gas due to impurity short-range and long-range potential and acoustical phonons (deformation and piezoelectric interaction) under the assumption that the shape of the confining potential is arbitrary.

Recent experiments on two-dimensional electron gas (2DEG) in quantum Hall regime have demonstrated that when nonideal current probes are used, the population of electron edge states can be unequal. In this case scattering between edge states (propagating in the same direction) affects four-probe measurements with nonideal voltage probe (the so-called anomalous quantum Hall effect).

Scattering of the edge states by irregularities of the boundary is discussed in Refs. 5 and 6, and scattering by impurities and phonons is discussed in Ref. 7. The confining
potential $U(y)$ in Ref. 7 was assumed to be parabolic. However the parabolic potential has no flat domain which corresponds to the interior of the sample. This accounts for the absence of quasibulk states and one cannot reveal the properties of scattering which appear when the Fermi level is close to a bulk Landau level. In this Letter we calculate the scattering length of the edge states due to impurities and phonons for an arbitrary potential $U(y)$. Further, the impurity potential in Ref. 7 was assumed to be of a short range, while it was shown, both theoretically$^{8,9}$ and experimentally$^{10,11}$ that for GaAs/Ga$_{1-x}$Al$_x$As heterostructures the dominant scattering mechanism is a long-range potential due to the remote ionized donors. This is why in this Letter we calculate the impurity scattering length for the long-range and for the short-range potential.

The wave function of the edge state is

$$\psi_{nk}(r) \sim \exp(ikz) \chi_{nk}(y) \varphi(z).$$  \hfill (1)

The location of the edge state with respect to the boundary of the 2DEG depends on the wave vector $k$. When $k \rightarrow +\infty$, state (1) transforms into a quasibulk Landau state, and its energy $E_{nk} = E_n = \hbar \omega_H (n + 1/2)$, where $\omega_H$ is the cyclotron frequency, and $\varphi(z)$ is the wave function of the spatial quantization of the 2DEG in the direction normal to the heterostructure interface.

**Impurity scattering**

In the Born approximation one can calculate the elastic scattering length for transition $n \rightarrow n'$

$$1/l_{n \rightarrow n'} = (1/v_n v_{n'}) \int dq_y <U U>_q |P_{nn'}|^2 / 2\pi,$$ \hfill (2)

where $<U U>_q$ is the 2D Fourier component of the scattering potential correlation function taken at the 2DEG plane, $q = (q_x, q_y)$, $v_n$ is the group velocity of the edge state $n$, and

$$P_{nn'}(q_y) = \int dy \chi_{n'}(y) \exp(-iq_y y) \chi_n(y).$$ \hfill (3)

In (2) one should set $q_x = \delta k_{nn'} = |k_n(E) - k_{n'}(E)|$, where $E$ is the energy of the initial state (see Fig. 1). The velocities $v$ and functions $\chi$ for states $n$ and $n'$ correspond to the energy $E = E_F$. Note that $l_{n \rightarrow n} = l_{n' \rightarrow n}$.

As in Refs. 8 and 9, we assume that the ionized donors are situated in a narrow layer separated from the 2DEG plane by the undoped spacer of thickness $z_0$. Because of the electron neutrality, the density of these donors (per cm$^{-2}$) is $N_s + N_d$, where $N_s$ is the density of the 2DEG and $N_d$ is the density of the depletion charge layer on the GaAs side; the latter is assumed to be uniformly doped by the acceptors with the net density (per cm$^{-3}$) $N_{AC}$. The correlation function $<U U>_q$ can then be written in the form$^9$

$$<U U>_q = \left( \frac{2\pi e^2}{\epsilon \epsilon_s(q) q} \right)^2 [(N_s + N_d) \exp(-2qz_0) + N_{AC}/2q].$$ \hfill (4)
where $\epsilon$ is the lattice dielectric constant which is assumed to be the same for GaAs and GaAlAs, $\epsilon(q) = 1 + q / q_s$ is the dielectric function of the 2DEG, and $q_s$ is the screening parameter. The first term in (4) corresponds to the long-range part of the scattering, while the second term corresponds to the short-range part.

For the long-range scattering one can proceed further under the assumption that $\delta k_{nn'} z_0 \gg 1$. In this case only small values of $q_y = (\delta k_{nn'} / z_0)^{1/2}$ contribute to the integral (2). Using this simplification, one can calculate the scattering length due to the long-range potential

$$1/l_{n\rightarrow n'}^L = (1/I_L) \exp(-2\delta k_{nn'} z_0) A_{nn'}^2,$$

where $A_{nn'} = P_{nn'}(0)$, and the nominal scattering length is given by

$$1/I_L = 2\pi^{3/2}[2\pi e^2/\hbar \epsilon(v_n v_{n'})^{1/2}][N_e + N_d](\delta k_{nn'} / z_0)^{1/2}/(\delta k_{nn'} + q_s)^2.$$

Because the factor $\exp(-2\delta k_{nn'} z_0)$ in (5) is small, the scattering is strongly suppressed compared to the case of zero magnetic field, even when the spatial separation between edge channels $\delta y_{nn'} = a_{HH} \delta k_{nn'}$, where $a_{HH}$ is the magnetic length, is not large compared to $a_{HH}$. For the short-range scattering Eq. (2) cannot be reduced to a more simple form without any assumption concerning the confining potential.

Now we consider the case of the smooth potential $U(y)$, where $U'(y) a_{HH} \ll \hbar \omega_H$. In this case we have

$$\tilde{\chi}_{nk'}(y) = \Phi_{n}(y - ka_{HH}^2), \quad \tilde{E}_{nk} = E_n + U(ka_{HH}^2).$$

where $\Phi_{n}$ is the harmonic oscillator wave function. In the smooth potential the overlap integral (3) can be calculated explicitly. Using (7), we have

$$A_{nn'}^2 = \frac{1 + (-1)^{n + n'} n(n!)}{\sigma^{2n + 2n'}} \exp(-\sigma^2/2),$$

where $\sigma = (y_{nn'}/a_{HH})^2 \gg 1$. The short-range scattering length $l^S_{n\rightarrow n'}$ becomes

$$1/l_{n\rightarrow n'}^S = (2\pi)^{-1/2}[2\pi e^2 / \hbar \epsilon(v_n v_{n'})^{1/2}]^2 N_{AC} a_{HH} \delta k_{nn'} (\delta k_{nn'} + q_s)^2 A_{nn'}^2.$$

FIG. 1.
The group velocity in the smooth potential is

$$v_{nk} = a_H^2 U'(ka_H^2).$$

(10)

It follows from (8) that in the smooth potential the dominant transition is \(n \rightarrow n + 1\).

**Acoustical phonon scattering**

Since the sound velocity \(s \ll v_n, v_{n'}\), the scattering is quasielastic, i.e., the energy of the emitted or absorbed phonon \(\hbar \omega \ll \hbar \omega_H\). Hence, in the transition \(n \rightarrow n'\) (see Fig. 1) the change of \(k\) is \(\delta k_{nn'}\). The minimal energy of the phonon is \(\Delta_{nn'} = \hbar \delta k_{nn'}\). In what follows we consider low temperatures \(T \ll \Delta_{nn'}\). Because of the phonon Bose factor and the Pauli exclusion principle, the phonon energy \(\hbar \omega\) is close to the threshold \(\Delta_{nn'}\). As a result, the calculation of the scattering length is greatly simplified. In the Born approximation for the deformation potential scattering (DA),

$$\frac{1}{l_{n \rightarrow n'}} = \frac{\Xi^2}{2\pi \hbar \rho s^2} A^{2}_{nn'} \frac{\delta k^2_{nn'}}{\hbar v_n v_{n'}} TF \left(\frac{\varepsilon}{T}, \frac{\Delta_{nn'}}{T}\right),$$

(11)

where

$$F(\xi, \eta) = (1/2)[\ln(1 + \exp(\xi - \eta)) + \exp(\xi) \ln(1 + \exp(-\xi - \eta))].$$

(12)

Here \(\Xi\) is the deformation potential constant, \(\rho\) is the crystal density, and \(\varepsilon = E - E_F\). The velocity \(v_{n'}\) and the function \(\chi_{n'}\) of the final state correspond to the energy of this state \(E = E'\). Equation (11) is valid if \(\exp(\varepsilon - \Delta/T) \ll \exp(\Delta/T)\) or, in other words, if \(|\varepsilon| < \Delta_{nn'}\) and if \(\varepsilon - \Delta_{nn'} \ll \Delta_{nn'}\). In the first case \(\hbar \omega - \Delta_{nn'} \approx T\), while in the second case \(\hbar \omega - \Delta_{nn'} \approx \varepsilon - \Delta_{nn'}\). It was assumed that \(T \gg ms^2\), and that \(\Delta_{nn'} \ll \hbar s/d\), where \(d\) is the scale of the function \(\varphi(z)\). For a GaAs/AlGaAs heterostructure \(d = 3\) nm, \(s = 5 \times 10^3\) cm/s, \(ms^2 = 0.1\) K, and \(\hbar s/d = 13\) K. Assuming \(\delta k_{nn'} = a_H^{-1}\), we have for \(H = 2T\): \(a_H = 18\) nm, \(\Delta_{nn'} = 2\) K and \(\hbar \omega_H = 39\) K. The inverse scattering length (3) is averaged near the Fermi energy:

$$\left\langle \frac{1}{l_{n \rightarrow n'}} \right\rangle = \int dE \left( -\frac{\partial f_0}{\partial E} \right) \frac{1}{l_{n \rightarrow n'}(E)}. $$

(13)

The function \(F\) increases exponentially with \(\varepsilon\) for \(\varepsilon > 0\) and the average value is due to the hot electrons \(\varepsilon \approx \Delta_{nn'} \gg T\), rather than thermal electrons \(\varepsilon \approx T\). Since \(\Delta_{nn'} \ll \hbar \omega_H\), we can set \(E = E_F\). With the above-mentioned assumptions for the DA scattering

$$\left\langle \frac{1}{l_{n \rightarrow n'}} \right\rangle_{DA} = \frac{1}{(\tau_{DA})_H} A^{2}_{nn'}(\delta k^2_{nn'}a_H)^3 s \frac{s}{v_nv_{n'}} \exp \left( -\frac{\Delta_{nn'}}{T} \right). $$

(14)

For the piezoelectric PA scattering the calculations are similar:

$$\left\langle \frac{1}{l_{n \rightarrow n'}} \right\rangle_{PA} = \frac{1}{(\tau_{PA})_H} A^{2}_{nn'}(\delta k^2_{nn'}a_H)^3 \frac{s}{v_nv_{n'}} \exp \left( -\frac{\Delta_{nn'}}{T} \right).$$

(15)

Here we define the nominal scattering times
\[ (1/\tau_{DA})_H = \Xi^2 / 4\pi \hbar \rho s^2 a_H^3 \]  
\[ (1/\tau_{PA})_H = (e\beta)^2 / 4\pi \hbar \rho s^2 a_H \]

where \( \beta \) is some piezoelectric modulus. For GaAs at \( H = 2 \) T we have \( (\tau_{DA})_H = 800 \) ps and \( (\tau_{PA})_H = 40 \) ps \( (\Xi^2 \) and \( \beta^2 \) were taken from Ref. 12). The exponential suppression of the scattering rate is due to the deficit of the free final states below \( E_F \).

To consider the case of the smooth potential, one has to substitute Eq. (7) for \( A_{odd} \) in (14) and (15). Comparing (14) or (15) with Eq. (7) in Ref. 7, we see that the corresponding equations agree only in the exponential factors from the overlap integral and from the deficit of the final states.

**Discussion**

Let us estimate \( l_{1-0} \) in the simplest case where the Fermi level is far from the Landau levels (i.e., the field \( H \) corresponds to the quantum Hall plateau), and the potential \( U(y) \) is not smooth; i.e., \( \delta k_{10} \approx a_{\mu}^{-1} \) and \( v_1, v_0 \approx a_{H} \omega_{H} \approx v_F \). To determine the dominant mechanism of the impurity scattering, it is sufficient to assume the characteristic lengths contained in the pre-exponential factors in (5) and (9) to be the same: \( a_{\mu} = q_0 = k_F^{-1} = \kappa^{-1} = 10 \) nm and \( N_d = N_s = 10^{12} \) cm\(^{-2} \). Comparing (5) and (9), we see that the long-range scattering dominates if the thickness of the spacer \( z_0 \) is less than

\[ z_0^* = (1/2\delta k_{nn'}) \ln(k^3/N_{AC}) \]  \( (17) \)

At \( N_{AC} = 10^{14} \) cm\(^{-3} \) we have \( z_0^* \approx 60 \) nm. To calculate \( l_{1-0} \), we assume \( \delta y_{10} \approx 1.5 a_{\mu} \), \( v_1 \approx v_0 \approx v_F/3 \), \( N_s = N_d = 3.5 \times 10^{12} \) cm\(^{-2} \) \( (k_F = 1.5 \times 10^6 \) cm\(^{-1} \), \( v_F = 2.6 \times 10^7 \) cm/s, and \( q_s = 2.0 \times 10^6 \) cm\(^{-1} \). The rate of the long-range impurity scattering depends strongly on the value of the parameter \( \delta k_{nn'} z_0 \). Setting \( z_0 = 40 \) nm, we have \( l_{1-0}^I \approx 3 \) \( \mu \)m at \( H = 2 \) T and \( l_{1-0}^I \approx 30 \) \( \mu \)m at \( H = 5 \) T, while the transport scattering length at \( H = 0 \), which corresponds to the typical value of the zero-field mobility \( \mu = 5 \times 10^5 \) cm\(^2/\)V·s, is \( \approx 5 \) \( \mu \)m. For the DA scattering \( l_{1-0} \approx 1000 \) \( \mu \)m exp(3 K/T) and for the PA scattering \( l_{1-0} \approx 5 \) \( \mu \)m exp(3 K/T). It follows from these calculations that the impurity scattering is strongly suppressed compared to \( H = 0 \), if \( H \) is high enough and if the phonon scattering is always weak. Note that the DA phonon scattering length estimated in Ref. 7 is much shorter. The reason for the difference is attributable principally to the choice of the electron-phonon interaction constant. The constant used in Ref. 7 is not related to the deformation potential constant \( \Xi \).

Impurity polarizability in silicon due to the magnetic degeneracy of donor states in a finite magnetic field

S. M. Dikman and D. I. Sidel'nikov

All-Union Scientific Research Institute for Current Sources

(Submitted 15 May 1991)

It is shown theoretically that the crossing of the energy levels $E_i(H)$ of shallow donor states of different symmetries due to the anisotropy of the effective mass makes it possible to experimentally observe an anomalously high impurity polarization that is independent of the electric field.

1. If a field $\vec{H}$ is directed along one of the principal axes of a crystal, calculations show that level crossings (points of magnetic degeneracy) occur in silicon even in the lowest part of the spectrum. In these cases the diagonal matrix elements of the dipole moment are nonzero, and in the presence of an electric field the true crossing is transformed into an anticrossing. The gap between the split levels is proportional to the field $\vec{E}$. This effect in a nonhydrogen-like spectrum is, in a certain sense, even more accidental than the "accidental" degeneracy and the linear Stark effect for the hydrogen atom, since in the former case it is not related to any conservation law.

In this article we present the results of a calculation of the eight lowest levels, for just those electrons for which the principal axis of the effective mass is oriented along the magnetic field. Each of the levels is thus twofold degenerate. Depending on the type of impurity, this intervalley degeneracy is lifted if the field of the neutral cell is taken into account, but the splitting, as is well known,\textsuperscript{1–3} is appreciable only for the ground state. Experiments\textsuperscript{4} show a considerably smaller splitting than, for instance, the calculations in Ref. 2, a result that is, in our view, a consequence of an unfortunate choice made by those investigators\textsuperscript{2} for the trial wave functions. Because of the axial symmetry, one can retain the same classification of the levels as in the problem of the hydrogen atom in a magnetic field\textsuperscript{5,6} or in the problem of a donor in a semiconductor without a field.\textsuperscript{1,7}

2. We used a variational method for the calculations. The dimensionless Schrödinger equation is written in the standard form\textsuperscript{2,6} (the anisotropy parameter for sili-
